

**1. Write a function called `print_full_name` that takes a first name and a last name as two parameters and prints them combined. Call it with three different pairs of names.**

**2. Write a function called `describe_box` that takes length, width and height as three parameters and prints their product as the volume. Call it once with 2, 3 and 4.**

*Hint: three parameters need three arguments, separated by commas in both the def line and the call.*

**3. Write a function called `show_temperature` that takes a city name and a temperature as parameters and prints a sentence using both. Call it once with the arguments in the correct order, then once with them swapped, and compare the two outputs.**

*Hint: swapping the order does not crash the program — it just puts each value in the wrong parameter.*

**4. Write a function called `print_square` that takes one number and prints its square. Using a for loop, call it once for every number in the list [1, 2, 3, 4, 5].**

*Hint: for `n` in [1, 2, 3, 4, 5]: `print_square(n)`*

**5. Write a function called `add_three` that takes exactly three numbers and prints their sum. Call it correctly once, then call it with only two numbers and note the exact error message Python shows.**

*Hint: the error will name which parameter did not receive an argument.*
