

1. Write a function called `multiply` that takes two numbers and returns their product. Store the result of `multiply(6, 7)` in a variable and print that variable.

2. Write a function called `is_positive` that takes one number and returns `True` if it is greater than 0, `False` otherwise. Print the result for 5 and for -3.

Hint: `return n > 0` is already a `True/False` expression on its own.

3. Write a function called `area` that takes length and width and returns their product. Print the combined result of `area(4, 5)` plus `area(2, 3)` in a single `print()` call.

Hint: `area(4, 5) + area(2, 3)` works directly because each call returns a real number.

4. Write a function called `half` that takes a number and returns it divided by 2. Print the result of calling `half` twice in a row on the number 40, by nesting one call inside the other.

Hint: `half(half(40))`

5. Write a function called `greet_user` that prints "checking name..." and then returns the message "Hello, " followed by the given name. Call it, store the result, and print only the stored result on its own line.

Hint: the function should both print something AND return something — notice they are two separate things.
