

1. Write a function `order_pizza` with a `size` parameter defaulting to "medium" that prints "One <size> pizza, please". Call it once with no argument and once with "large".
2. Write a function `calc_discounted` that takes a `price` and a `discount` parameter defaulting to 10, and prints the price after that percentage discount. Call it with just a `price`, then again with a `price` and a `discount` of 20.
*Hint: $price - (price * discount / 100)$*
3. Write a function `repeat_text` that takes a `text` parameter and a `times` parameter defaulting to 3, and prints the text repeated that many times. Call it with just `text`, then with `text` and a custom `times` value.
Hint: `text * times` repeats a string that many times.
4. Write a function with three parameters where the first has no default and the last two do. Call it three different ways: with only the required argument, with the required argument plus one more, and with all three.
5. Explain in a comment why the following definition fails before it is ever called: `def greet(greeting="Hi", name): print(greeting, name)` — then rewrite it correctly.
Hint: every parameter without a default must come before every parameter that has one.
